

## CENTRIFUGAL PUMP

### TECHNICAL FIELD

The present invention relates to a pump of a rotodynamical type  
5 comprising at least one impeller arranged in a pump housing driven by  
an electrical motor.

### BACKGROUND OF THE INVENTION

Pumps of the above mentioned kind can roughly be divided into two  
10 types: centrifugal pumps and axial pumps.

The centrifugal pump comprises an impeller consisting of a hub and at  
least one cover disc with a number of vanes arranged to the hub, a so  
called open impeller. A so called closed impeller is arranged with two  
15 cover discs with vanes between. The liquid is in both cases sucked in  
axial direction in the centre of the impeller and leaves the impeller at  
the periphery in mainly tangential direction.

The axial pump differs from the above mentioned centrifugal pump in  
20 that the liquid leaves the pump mainly in axial direction. This deflection  
is done with the aid of a number of guide rails arranged downstream in  
the pump housing. The guide rails normally also serves as supporting  
elements in the construction of the pump housing.

25 During pumping of polluted liquids such as waste water, water in  
mines, at construction sites etc, the pumping is often disturbed by the  
pollution. This may cause clogging of pump impellers and pump  
 housings and also often lead to considerable wear problem.

30 During pumping of waste water that may contain elongated objects  
such as rags, there are several methods for solving the problem. An  
open pump impeller with only one cover disc is then preferred, but even  
so external measures are required. One may be to run the pump

impeller backwards at certain intervals. Another is to arrange some sort of cutting means in front of the intake. US 5,516,261 discloses an open pump impeller for pumping of waste water where the bottom of the pump housing is arranged with a spirally shaped groove, which leads pollutants out towards the periphery where they can cause less damage.

During pumping where high lifting heights are required, for example in mines, closed pump impellers are used, i.e. such with two cover discs, an upper and a lower as well as intermediate vanes. Such impellers have generally speaking higher efficiency than open impellers at high pressure heights. On the other hand, closed impellers have a lesser lead-through, which means higher risk for clogging.

The pollution that is present during pumping in mines often contain elements of highly abrasive material, implying that the material in both pump impeller and pump housing are exposed to great stress. These problems can partly be solved by special surface treatment or hardening of the different components, but it is naturally a desire to ensure that the abrasive particles leave the pump housing as fast as possible in order to avoid unnecessary wear. Further, the geometrical design of the parts that are important for the pumping function of central importance in order to reduce the wear.

## BRIEF DESCRIPTION OF THE INVENTION

The aim of the present invention is to achieve a solution of the wear problem by a certain design of the bottom of the pump housing.

According to a main aspect of the invention the aim is solved by a device according to claim 1.

Advantageous features of the invention are the subject of the dependent claims.

According to a main aspect of the invention it is characterized by a centrifugal pump for pumping of liquids containing pollutions mainly in the form of solid particles, which pump comprises a drive unit, a hydraulic unit, whereby the hydraulic unit comprises a pump housing and a pump impeller rotationally arranged inside the housing, the  
5 pump impeller comprising an upper and a lower cover disc and a number of intermediate vanes, wherein a bottom wall of the pump housing, having a central inlet opening, is arranged with at least one spirally extending back flow affecting means on the side facing the lower  
10 cover disc, extending parts of or full turns around the inlet opening.

The back flow extending means could be arranged as grooves and/or ridges in the bottom wall.

15 Further, a wall part of the back flow affecting means facing towards the inlet forms an angle with the plane of the bottom wall which preferably should be in the range 85 to 95 degrees.

The back flow affecting means according to the invention acts to affect  
20 the back flow, containing pollutions, entering the space between the impeller and the bottom wall so that the pollutions, such as abrasive particles, to a great extent are prevented from reaching the gap, or the amount at least greatly reduced. Most of the particles will enter the grooves or space between the ridges and due to the spiral shape, the  
25 particles will be transported to the periphery of the bottom plate, and out through the outlet.

It has been found that the distance between the top surface of the ridges or plateau between the grooves and the lower cover disc should  
30 be in the indicated range. A too large distance will not create the desired effect, and a too narrow gap will increase the speed of the back flow, deteriorating the effect.

It has also shown that a rather steep back surface creates an increased effect, possibly creating an increased disturbance on the back flow.

These and other aspects of, and advantages with, the present invention  
5 will become apparent from the following detailed description and from the accompanying drawings.

#### DETAILED DESCRIPTION OF THE DRAWINGS

In the following detailed description of the invention, reference will be  
10 made to the accompanying drawings, of which

Fig. 1 is an axial cross-section through a pump according to the invention, and

15 Fig. 2 is a detail taken from the ring of Fig. 1,

Fig. 3 is a modification of the detail of Fig. 2, and

Fig. 4 is the bottom of the pump housing seen from above.

#### DETAILED DESCRIPTION OF THE INVENTION

The pump shown in Fig. 1 comprises a drive shaft 10 connected to an electrical motor (not shown) for driving the pump. To the lower end of the shaft a pump impeller 12 is mounted, comprising upper 14 and  
25 lower 16 cover discs, vanes 18 and back vanes 19. The above mentioned components are mounted in a pump housing 20, having a bottom wall 22, an inlet 24 and an outlet 26. The pump impeller 12 is mounted such in the pump housing that there is a gap 28 between the peripheral surface of the lower cover disc 16 and an inner side wall of the pump  
30 housing 20, a space 29 between the lower disc and the bottom wall as well as a gap 30 between a lower surface of the lower cover disc 16 and an upper surface of the bottom wall 22.

According to the principles for a centrifugal pump, the liquid is sucked in axially through the inlet 24 and leaves the pump through the outlet 26 according to flow arrows A, B and C. Because the pressure is much higher at the outlet than at the inlet, however a certain flow D will  
5 always flow back through the gap 28 and into the space 29 between the lower cover disc 16 and the bottom 22 of the pump housing. A part of this flow E passes the gap 30 back to the inlet, while a part of the flow F is again led outwards on the underside of the cover disc 16, so called boundary layer flow. A boundary layer flow is also present along the  
10 bottom wall, but directed inwards.

The back flow D creates losses and also results in that pollution, abrasive particles and the like, are gathered under the cover disc because particles of a certain size cannot pass the gap 30. This  
15 gathering of particles will then wear against pump impeller as well as against the bottom of the pump housing during running of the pump. Particles entering the gap 30 will act as grinders, with heavy wear on the surfaces of the gap. This may in a short time mean a considerable deterioration of the pump capacity because the gap is worn larger.

20 In order to ascertain a feeding of abrasive particles that have entered the space 29 between the lower cover disc and the bottom wall out towards the periphery for further transport towards the pump outlet, the bottom wall of the pump housing facing the lower surface of the  
25 lower cover disc of the impeller is arranged with one or several swept flow affecting means, in the embodiment shown spiral grooves 32 divided by ridges. In the embodiment shown the grooves wind spirally around the inlet opening 24 several turns. The flow affecting means are swept such that the radial distance  $r$  from the centre is increased in the  
30 rotational direction  $R_d$  of the impeller, as seen in Fig. 4.

The grooves will affect the main flow D and the particles contained in the flow such that the water volume entering the space is moved in a

tangential direction, due to the rotation of the impeller, and where the water volume is moved along the swept flow affecting means. This action causes the particles in the water to be moved in the grooves between the ridges in the rotational direction and due to the swept, and preferably spiral, shape of the grooves the pollutions will be fed along the grooves and out through the outlet, or at least be prevented from gathering in the gap. Because of the present invention the radial component of the boundary layer flow along the bottom wall is affected such that it is directed more in the tangential direction, thus also affecting the part of the water volume in the bottom of the grooves to be moved in the direction of the swept back flow affecting means.

During tests there are certain aspects that seem to affect the process in the gap and to what extent the water volume in the grooves are affected. For example the distance  $d$ , Fig. 2, between the lower surface of the lower cover disc and the top surfaces of the ridges between the grooves seem to have an influence. Tests have shown a good result of the process when the distance  $d$  is in the range of  $1/3$  to  $2/3$  of the distance between the bottom of the grooves and the lower surface of the lower cover disc, but this is not to be regarded as limiting to the invention. For example the distance could be smaller if the tolerances of the impeller wheel and the bottom wall where to be tighter, or if the bottom wall, or at least the ridges, where made of a resilient material such as rubber, which would allow some contact between the parts during use. The depth of the grooves and the distance between ridges in the radial direction, thus the volume in the grooves, has to be taken into account so that preferably the whole water volume is affected by the process.

The sweeping angle  $\alpha$  of the spiral ridges also have an influence in affecting the direction of the flow and the feeding of particles in the grooves. It should in principle be possible to have straight edges of the flow affecting means with an angle to the radial direction, even though

this design is not optimal for transporting particles towards the periphery of the impeller wheel.

- The back surfaces of the ridges also affect the process and tests have shown that an angle  $\beta$  between the back surface and a plane parallel with the bottom of the pump housing should preferably be in the range 85 to 95 degrees, Fig. 2. For some types of impeller wheels however, such as those having a conical shape, and a corresponding shape to the bottom wall, Fig. 3, this range is not obtainable, at least not with cast metal bottom wall. Tests have however shown a satisfactory result with a design according to Fig. 3. If the bottom wall according to Fig. 3, or at least the flow affecting means, where to be made of a resilient material the ridges could be cast with an angle according to the above range.
- With the right design of the ridge and groove a separating effect is obtained that leads to fewer and smaller particles in comparison with the rest of the liquid, in turn meaning a reduced wear. In view of the above the flow affecting means could either be grooves machined or cast in the bottom plate, or ridges attached to or cast in the bottom plate.
- Depending on the design of the bottom plate the ridges or grooves may have different design. The bottom plate shown in the drawings is made with integral back flow affecting means, but of course the back flow affecting means could be made as a separate part which is attached in a suitable way to the bottom wall. In order to increase the effect the lower cover disc may be arranged with back vanes turned towards the bottom wall containing the grooves/ridges. Such back vanes however constitute a certain energy loss and are therefore used only under especially difficult conditions.
- It is to be understood that the embodiment described above and shown in the drawings is to be regarded as a non-limiting example of the invention and that it may be modified in many ways within the scope of the patent claims.
